ABSTRACT

We have calculated the effects of large scale solar flows like the meridional circulation, giant convection cells and solar rotation on the helioseismic splitting coefficients using quasi-degenerate perturbation theory (QDPT). Our investigation reveals that the effect of poloidal flows like the large scale meridional circulation are difficult to detect in observational data of the global acoustic modes since the frequency shifts are much less than the errors. However, signatures of large scale convective flows may be detected if their amplitude is sufficiently large by looking for frequency shifts due to nearly degenerate modes coupled by convection. In this comprehensive study, we attempt to put limits on the magnitude of flow velocities in giant cells by comparing the splitting coefficients obtained from the QDPT treatment with observational data.

1. Introduction

Solar convection is believed to be organized in a variety of spatial and temporal scales ranging from granules (size ~ 1 Mm, 0.2 hr lifetime), mesogranules (size ~ 10 Mm, 3 hr lifetime), supergranules (size ~ 30 Mm, 1 day lifetime) to the giant cells (size ≥ 100 Mm, 1 month lifetime). The power spectra of convective velocities show distinct peaks representing granules and supergranules but no distinct features at wavenumbers representative of mesogranules or giant cells (Wang 1989; Chou et al. 1991; Straus, Deubner, & Fleck 1992; Straus & Bonaccini 1997; Hathaway et al. 2000). Numerical simulations of solar convection routinely show the existence of mesogranules and giant cells (Miesch et al. 2000; Miesch et al. 2008). In this study we will only concentrate on the theoretical frequency shifts in global

¹Now at NORDITA, Stockholm 106 91, Sweden

surface gravity and acoustic modes, denoted f- and p-modes respectively due to interaction with large scale flows namely the giant cells, the meridional circulation and rotation. The meridional circulation, believed to play an important role in magnetic flux transport by Solar dynamo modelers (Choudhuri, Schüssler & Dikpati 1995; Dikpati & Charbonneau 1999; Chatterjee, Nandy & Choudhuri 2004) was observed at the solar surface by Doppler measurements of photospheric lines (Duvall 1979; LaBonte & Howard 1982; Komm, Howard & Harvey 1993; Hathaway 1996) and later by using techniques of ring diagram and time-distance helioseismology (Giles et al. 1997; Basu, Antia & Tripathy 1999; González Hernández et al. 1999). These studies can only measure the flow velocity in the near surface layers. This flow having a maximum surface velocity of 30 m s^{-1} is apparently poleward all the way from the equator to the poles at the Solar surface. Conservation of mass requires existence of a return flow advecting mass from the poles to the equator somewhere below the surface. The dynamo models assume that the return flow occurs near the base of the convection zone, but there is no direct evidence about where the return flow is located. It is believed that the only hope of detecting such a return flow is by analyzing the effect of the meridional circulation on the global helioseismic acoustic modes (Roth & Stix 2008). Their investigation using quasi degenerate perturbation theory showed that theoretical p-mode frequency shifts due to meridional circulation would be $\sim 0.1 \mu\text{Hz}$. Such large frequency shifts may not be expected from the observed magnitude of meridional flows. For the sake of comparison, the equatorial rotational velocity at the Solar surface is $\sim 2000 \text{ m s}^{-1}$ and gives rise to frequency shifts $\sim 450 \times m \text{ nHz}$ as a linear function of azimuthal order m . Further, since the first order contribution from meridional flow calculated using the degenerate perturbation theory vanishes, one would expect the effect to be even smaller than what is suggested by the velocity. Thus it is necessary to reexamine these calculations.

Quasi degenerate perturbation theory (QDPT) was applied to calculate shifts due to flows and asphericity in Solar acoustic frequencies by Lavelly & Ritzwoller (1992). We

have used the same formulation to calculate the p-mode frequency shifts due to differential rotation, meridional circulation and giant cells of convection. In contrast to results of Roth & Stix (2008), our results indicate a maximum shift of about 1 nHz for a similar meridional circulation encompassing the entire solar convection zone. Traditionally, only degenerate perturbation theory (DPT) has been used to calculate the effect of rotation on the p-modes. Woodard (1989) and Vorontsov (2007) applied QDPT to calculate mixing of eigenfunctions due to rotational coupling of p-modes and concluded that the expected line profiles of the composite modes in the Solar power spectra are not distorted significantly. In this work, we use a different approach to examine if the use of quasi degenerate perturbation theory introduces significant corrections in the frequency shifts over that obtained from degenerate perturbation theory. It is necessary to check this as inversion techniques for calculating rotation rate in the solar interior are based on degenerate perturbation theory. Helioseismic inversion for rotation is also insensitive to the N–S asymmetric component of rotation. This is because in the degenerate perturbation theory, this effect also gives zero contribution. The N–S antisymmetric component of rotation has been studied near the surface and is found to be small. In this work we wish to examine its effect to check if its contribution to frequency shift are indeed small.

The giant convective cells have always been elusive to observations at the solar surface. In the past there have been studies which have failed to detect giant cell motions (LaBonte, Howard & Gilman 1981; Snodgrass & Howard 1984; Chiang, Petro & Foukal 1987) as well as those hinting at their existence (Cram, Durney & Guenther 1983; Hathaway et al. 1996; Simon & Strous 1997). With the availability of Dopplergrams from SOHO/MDI, it became possible to study such long-lived and large scale features more reliably. Beck, Duvall & Scherrer (1998) were able to detect giant cells at the solar surface with large aspect ratio (~ 4) and velocities $\sim 10 \text{ m s}^{-1}$ using the MDI data. Hathaway et al. (2000) used spherical harmonic spectra from full disk measurements to detect long-lived power at $l \leq 64$.

This means that the spatial extent of the features were $\sim 2\pi R_{\odot}/\sqrt{l(l+1)} \geq 70$ Mm. Later Ulrich (2001) identified these long-lived features not as giant cells but higher order components of the torsional oscillation. Interestingly it was earlier proposed by Snodgrass & Wilson (1987) that torsional oscillations occur due to modulation of differential rotation by the Coriolis force arising from meridional motions of giant cells.

The elusiveness of the giant cell features in the surface velocities lead modelers to speculate about the subsurface nature of the giant cell motions (Latour, Toomre & Zahn 1981). Roth & Stix (1999, 2003) used QDPT to calculate the effect of giant cells on p-modes and claimed that giant cells could be found by modeling the asymmetries and line broadening in the Solar power spectrum. They claimed that finite line width of the multiplets would limit the detection of the frequency splittings to vertical velocity amplitude of 100 m s^{-1} or larger. However, Roth, Howe & Komm (2002) claimed that giant cells could be detected with current inversion methods of global helioseismology as long as they exceed an amplitude of 10 m s^{-1} . Usual inversion procedure for rotation neglects giant cells and assumes that the odd splitting coefficients arise only from rotation. If there are additional contributions to these coefficients, rotation inversions would not give correct results. According to Roth, Howe & Komm (2002) the effect of giant cells would appear as distortions in the rotation inversion if their velocities are $\geq 10 \text{ m s}^{-1}$. However, using the same technique of QDPT we find that with the present global helioseismic data we can put an upper limit of $50\text{--}100 \text{ m s}^{-1}$ on the vertical velocity associated with giant cell flows. This is mainly because our calculations show much smaller effects from giant cells.

This paper is organized as follows. In §2 we define zonal and poloidal flows inside the Sun, while §3 discusses the quasi degenerate perturbation theory, its differences from degenerate theory as well as the details of our calculations. We present our theoretical results and compare them with present f- and p-mode data from both GONG and

SOHO/MDI instruments in §4. Finally conclusions are described in §5.

2. Zonal and Poloidal Solar Flows

Following earlier works (Lavelly & Ritzwoller 1992; Roth, Howe & Komm 2002) we express the velocity field in terms of spherical harmonics. For completeness, we give the expression here again.

$$\begin{aligned} \mathbf{v}(r, \theta, \phi) = & \operatorname{Re}[u_s^t(r)Y_s^t(\theta, \phi)\hat{\mathbf{r}} + v_s^t(r)\nabla_h Y_s^t(\theta, \phi) - \\ & w_s^t(r)\hat{\mathbf{r}} \times \nabla_h Y_s^t(\theta, \phi)]. \end{aligned} \quad (1)$$

The quantities u_s^t, v_s^t and w_s^t determine the radial profiles of the flows and ∇_h is the horizontal gradient operator. The Re refers to using only the real part of the spherical harmonics as in,

$$\operatorname{Re}[Y_s^t(\theta, \phi)] = \begin{cases} [Y_s^{-t}(\theta, \phi) + Y_s^t(\theta, \phi)]/2 & \text{if } t \text{ is even,} \\ [Y_s^{-t}(\theta, \phi) - Y_s^t(\theta, \phi)]/2 & \text{if } t \text{ is odd.} \end{cases} \quad (2)$$

The first two terms in equation (1) define the poloidal component of the flow whereas the last term is the toroidal component. By the poloidal component, we imply the meridional and non-zonal toroidal flows (average over ϕ direction is zero) e.g., (i) the meridional circulation which carries mass poleward near the surface and sinks near the poles and (ii) the giant convection cells, respectively. These flows are also called large scale flows to distinguish them from other small scale flows like the turbulent eddies which are of the size smaller than the typical scale of global modes used in helioseismology. In presence of only the poloidal flow ($w_s^t = 0$) we can apply the equation of mass conservation $\nabla \cdot (\rho_0 \mathbf{v}) = 0$ to get a relation between $u_s^t(r)$ and $v_s^t(r)$ e.g.,

$$v_s^t(r) = \frac{1}{r} \frac{\partial}{\partial r} \left[\frac{\rho_0 r^2 u_s^t(r)}{s(s+1)} \right]. \quad (3)$$

Here $\rho_0(r)$ is the density in a spherically symmetric solar model. So now it only remains to choose $u_s^t(r)$ appropriately and $v_s^t(r)$ will be determined by equation (3). We choose the radial profile of $u_s^t(r)$ as given by equation (19) of Roth, Howe & Komm (2002):

$$u_s^t(r) = \begin{cases} u_0 \frac{4(R_{\text{top}}-r)(r-r_b)}{(R_{\text{top}}-r_b)^2} & \text{if } r_b \leq r \leq R_{\text{top}}, \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

Here r_b and R_{top} define the boundaries of region where the flow is confined. The tangential component v_s^t also vanishes outside these boundaries. Further, because of very small density scale height near the solar surface, v_s^t increases very rapidly near the top boundary and its maximum value depends on the choice of R_{top} . For the meridional flow such a behavior has not been seen in the actual observed profile (e.g., Basu, Antia & Tripathy 1999). In most of our computations we use $r_b = 0.7R_{\odot}$, the approximate position of the base of the convection zone, while R_{top} is taken to be the top of the solar model used in this work, which is around $1.0017R_{\odot}$. With this choice most of the steep variation in v_s^t occurs above $r = R_{\odot}$ and the variation is probably more reasonable below the solar surface.

The radial profile of the vertical velocity and the horizontal velocity for the upper boundary at $R_{\text{top}} = R_{\odot}$ is shown in Figure 1. We wish to point out that Roth, Howe & Komm (2002) have used an upper boundary at $R_{\text{top}} = 0.99R_{\odot}$ in equation (4). This avoids the region with small density scale height and hence the maximum value of $v_s^t(r)$ is smaller. In this work we have used a standard solar model with the OPAL equation of state (Rogers & Nayfonov 2002) and OPAL opacities (Iglesias & Rogers 1996) and use the formulation due to Canuto & Mazzitelli (1991) to calculate the convective flux. The flow obtained using equation (4) consists of only one cell in the radial direction. Following Roth, Howe & Komm (2002) we also use giant cells with a horizontal wave number $s = 8$. The streamlines of the flow for $s = 8, t = 8$ as well as for $s = 8, t = 0$ are given in Figure 7 of Roth, Howe & Komm (2002).

The differential rotation constitutes the zonal toroidal flows with $t = 0$ in last term of equation (1). The radial and angular dependence of uniform rotation is given by $w_1^0(r)\partial_\theta Y_1^0(\theta, \phi)$ and that of differential rotation with $s = 3$ is given by $w_3^0(r)\partial_\theta Y_3^0(\theta, \phi)$ respectively. Rotation affects the p-modes in two ways: (i) Coriolis force which is linear in rotation rate, Ω and (ii) centrifugal force which is quadratic in Ω . To first order, the linear term gives only odd splitting coefficients, while the centrifugal term gives only even splitting coefficients. The effect of centrifugal force is of second order compared to (i) and has been calculated by Antia et al. (2000). In this work we would consider only the linear term due to Coriolis force, or advection in an inertial frame, though we apply QDPT to calculate second order corrections due to rotation.

3. Perturbation of f- and p-modes

The eigenfunctions and eigenfrequencies for a standard solar model can be calculated using perturbative or variational methods. We follow the approach of Lavelly & Ritzwoller (1992) and use the quasi-degenerate perturbation theory, as opposed to degenerate perturbation theory, to determine these quantities. For meridional flow this is necessary as the degenerate perturbation gives zero frequency shifts. Let the eigenfunctions of the operator $\mathcal{L}_0$ governing the seismic oscillations in a standard solar model be called the non-rotating standard solar model (NRSSM) eigenfunctions. We shall see in §3.1 how to appropriately choose the set of NRSSM eigenfunctions for quasi-degenerate and degenerate treatments.

3.1. Quasi-degenerate perturbation theory

The difference between QDPT and DPT lies in the choice of the set of NRSSM eigenfunctions ($\mathbf{s}_{\mathbf{k}}$), whose linear combinations are used to express the perturbed eigenfunctions ($\mathbf{s}'_{\mathbf{k}}$) e.g.,

$$\mathbf{s}'_{\mathbf{k}} = \sum_{k' \in K} a_{k'} \mathbf{s}_{\mathbf{k}'}. \quad (5)$$

In DPT only the eigenfunctions from the standard solar model which are *exactly* degenerate constitute the eigenspace K . In contrast to this in QDPT the set consists of all eigenfunctions of the standard solar model with *nearly* degenerate frequencies. It is well known that simple harmonic oscillators couple strongly only if the natural uncoupled frequencies of the oscillators are nearly degenerate. Hence it is important to determine which of the NRSSM eigenfunctions should be included in the analysis. Let the eigenspace of the suitable eigenfunctions be called K . Qualitatively, the quasi-degenerate condition implies that we include an eigenfunction $\mathbf{s}_{nlm}(= \xi_{nl}(r)Y_l^m \hat{\mathbf{r}} + \eta_{nl}(r)\nabla_h Y_l^m) \in K$ iff $|\omega_{nlm} - \omega_{\text{ref}}| < \epsilon$, where ϵ is the radius of the neighborhood about the central frequency. We have generally used $\epsilon = 100 \mu\text{Hz}$ in this work. This is comparable to asymptotic spacing between two consecutive modes in radial order n . Moreover no significant change in calculated frequency shifts is observed for $\epsilon > 100 \mu\text{Hz}$. Here ω_{ref} is the frequency of the central eigenmode for which we require the frequency shift. The size of the eigenspace K will be determined by the (i) desired level of accuracy which is set by ϵ and (ii) the selection rules of the perturbation operator.

In the NRSSM the frequencies are independent of the azimuthal order m and this degeneracy is lifted by departures from spherical symmetry due to rotation or magnetic field. Helioseismic data traditionally give the splitting coefficients for all modes that are

detected. These coefficients are defined by (e.g., Ritzwoller & Lavelly 1991)

$$\omega_{nlm} = \omega_{nl} + \sum_q a_q^{(nl)} \mathcal{P}_q^l(m), \quad (6)$$

where ω_{nl} is the mean frequency of the multiplet, $\mathcal{P}_q^l(m)$ are the orthogonal polynomials of degree q and $a_q^{(nl)}$'s are the so called splitting coefficients.

The equations of motion for a mode k with eigenfrequency ω_k for a NRSSM and a model perturbed by addition of differential rotation and/or large scale flow can be respectively represented by,

$$\mathcal{L}_0 \mathbf{s}_k = -\rho_0 \omega_k^2 \mathbf{s}_k, \quad (7)$$

$$\mathcal{L}_0 \mathbf{s}'_k + \mathcal{L}_1 \mathbf{s}'_k = -\rho_0 \omega_k'^2 \mathbf{s}'_k, \quad (8)$$

where ω'_k is the perturbed frequency and $\mathbf{s}'_k$ given by equation (5) is the perturbed eigenfunction. Taking scalar product with $\mathbf{s}_j$ in equation (8) and using the notation $\mathcal{H}_{jk'} = -\int \mathbf{s}_j^\dagger \mathcal{L}_1 \mathbf{s}_{k'} dV$ and the definition $\mathcal{L}_1 \mathbf{s}_k = -2i\omega_{\text{ref}}\rho_0(\mathbf{v} \cdot \nabla) \mathbf{s}_k$, we obtain the matrix eigenvalue equation,

$$\sum_{k' \in K} \left\{ \mathcal{H}_{jk'} + \delta_{k'j}(\omega_k'^2 - \omega_{\text{ref}}^2) \right\} a_{k'} = (\omega_k'^2 - \omega_{\text{ref}}^2) a_j, \quad (9)$$

with, eigenvalue $\lambda = (\omega_k'^2 - \omega_{\text{ref}}^2)$ and eigenvector $X_j = \{a_j\}$. Here ω_{ref} is a reference frequency which approximates ω'_k . In this work we use $\omega_{\text{ref}} = \omega_k$, the frequency of the mode being perturbed. It will be clear from §3.2 that the perturbation matrix $[\mathcal{H}_{n'n, l'l}^{m'm}]$ is Hermitian for both differential rotation and poloidal flows. For example, if we consider only two modes with frequencies ω_1 and ω_2 , then quasi degenerate perturbation theory gives the following coupling matrix for the mode ω_2 ,

$$\begin{bmatrix} \mathcal{H}_{11} - \Delta & \mathcal{H}_{12} \\ \mathcal{H}_{21} & \mathcal{H}_{22} \end{bmatrix} \quad (10)$$

with $\Delta = \omega_2^2 - \omega_1^2$. We are interested in the eigenvalues λ of $[\mathcal{H}_{ij}]$ corresponding to perturbation in ω_2 which may be easily shown to be,

$$\lambda \sim \mathcal{H}_{22} - \frac{|\mathcal{H}_{12}|^2}{\mathcal{H}_{11} - \mathcal{H}_{22} - \Delta} . \quad (11)$$

Let ω'_2 be the modified frequency of the mode which initially has a frequency ω_2 . Then from equation (11) we have,

$$\omega'_2 \sim \left[\omega_2^2 + \mathcal{H}_{22} - \frac{|\mathcal{H}_{12}|^2}{\mathcal{H}_{11} - \mathcal{H}_{22} - \Delta} \right]^{\frac{1}{2}} . \quad (12)$$

If DPT were used then the last term involving off-diagonal term $\mathcal{H}_{12}$ will not be present and hence this term gives the correction arising from using the QDPT. It is clear that this correction can be large if the two modes are nearly degenerate.

If $|H_{12}| \approx |\Delta|$, then the frequency shift due to use of QDPT would be of order of Δ/ω_2 , which is comparable to the difference $\omega_2 - \omega_1$. On the other hand if $|H_{12}| \ll |\Delta|$, then the frequency shift would be much less. For a typical p-mode the spacing $\omega_2 - \omega_1$ is of order of a few μHz . For a rotation velocity of 2000 m s^{-1} , the frequency shift is of the order of $450m \text{ nHz}$, which would define the magnitude of diagonal terms. Thus for meridional flow with averaged velocity of 20 m s^{-1} we may expect the matrix elements $H_{12}/\omega_2 \sim 4.5l \text{ nHz}$. However, in this case the diagonal elements are zero and we need the off-diagonal element which involves cross product of two different eigenfunctions in the integration (cf., Eq. 15) and (for the same velocity) this integral would be more than order of magnitude smaller than that in diagonal term for rotation. Thus the magnitude of H_{12} would be an order of magnitude less, giving a frequency shift of order of $0.2l^2/(\omega_2 - \omega_1) \text{ nHz}$, taking the maximum value of m . For $l \approx 100$ this would give a shift of order of a few nHz. This is much smaller than that obtained by Roth & Stix (2008).

In the next section we shall give the expression for the perturbation matrix elements $[\mathcal{H}_{nn',ll'}^{mm'}]$ due to rotation as well as poloidal flows to be used for solving the eigenvalue

equation (9).

3.2. Calculating the perturbation matrix

The Wigner-Eckart theorem (equation 5.4.1 of Edmonds 1960) states that the general matrix element of any tensor perturbation operator can be expanded in terms of Wigner $3j$ symbols whose coefficients of expansion are independent of azimuthal order m and m' .

$$\mathcal{H}_{n'n,l'l}^{m'm} = (-1)^{m'} \begin{pmatrix} l' & s & l \\ -m' & t & m \end{pmatrix} (n'l' || \mathfrak{L}_s^t || nl). \quad (13)$$

The coefficient of the Wigner $3j$ symbol in equation (13) due to coupling by the differential rotation is given by,

$$(n'l' || \mathfrak{L}_s^t || nl) = 8\pi\omega_{\text{ref}}(1 - (-1)^{l+l'+s}) \times \gamma_l \gamma_{l'} \int_0^{R_\odot} \gamma_s w_s^0 \rho r^2 dr T_s(r), \quad (14)$$

where,

$$T_s(r) = -\frac{1}{r} \left\{ \xi' \eta + \eta' \xi - \xi' \xi - \frac{1}{2} \eta' \eta [l(l+1) + l'(l'+1) - s(s+1)] \right\} \times \Gamma_l \Gamma_{l'} \begin{pmatrix} l' & s & l \\ -1 & 0 & 1 \end{pmatrix}, \quad (15)$$

$\Gamma_q = \sqrt{q(q+1)/2}$ and $\gamma_q = \sqrt{(2q+1)/4\pi}$. ξ and η are radial and horizontal components of the eigenfunction defined in §3.1.

Similarly we have derived the coefficient of the Wigner $3j$ symbol in equation (13) due to coupling by the large scale poloidal flow,

$$(n'l' || \mathfrak{L}_s^t || nl) = 8\pi i \omega_{\text{ref}}(1 + (-1)^{l+l'+s}) \times$$

$$\gamma_l \gamma_{l'} \int_0^{R_\odot} \gamma_s u_s \rho r^2 dr \left[R_s - \frac{\partial H_s}{\partial r} \right], \quad (16)$$

where,

$$\begin{aligned} R_s(r) = & \frac{1}{4} \left(\xi' \frac{\partial \xi}{\partial r} - \frac{\partial \xi'}{\partial r} \xi \right) \begin{pmatrix} l' & s & l \\ 0 & 0 & 0 \end{pmatrix} + \\ & \frac{1}{2} \Gamma_l \Gamma_{l'} \left(\eta' \frac{\partial \eta}{\partial r} - \frac{\partial \eta'}{\partial r} \eta \right) \begin{pmatrix} l' & s & l \\ -1 & 0 & 1 \end{pmatrix}, \end{aligned} \quad (17)$$

$$\begin{aligned} H_s(r) = & \frac{1}{2} [l(l+1) - l'(l'+1)] \times \\ & \left[\frac{1}{2} \xi \xi' \begin{pmatrix} l' & s & l \\ 0 & 0 & 0 \end{pmatrix} - \eta \eta' \Gamma_l \Gamma_{l'} \begin{pmatrix} l' & s & l \\ -1 & 0 & 1 \end{pmatrix} \right] \\ & - \eta' \xi \Gamma_{l'} \Gamma_s \begin{pmatrix} l' & s & l \\ -1 & 1 & 0 \end{pmatrix} + \xi' \eta \Gamma_l \Gamma_s \begin{pmatrix} l' & s & l \\ 0 & 1 & -1 \end{pmatrix}. \end{aligned} \quad (18)$$

The selection rules for the Wigner $3j$ symbol to be non zero are,

1. $p/2 \geq \max(l, l', s)$, where $p = l + l' + s$,
2. $m - m' + t = 0$.

The selection rule for non trivial reduced matrix elements due to differential rotation is given by,

3. $l + l' + s$ must be odd.

This means that the $\partial_\theta Y_3^0$ component of differential rotation couples modes with $l' = l, l \pm 2$. The set of modes that constitutes the eigenspace K must follow selection rules (1), (2) and (3) and the quasi-degenerate condition $|\omega_{nlm} - \omega_{\text{ref}}| < 100 \mu\text{Hz}$. The selection rule for reduced matrix elements due to large scale poloidal flow to be non zero is

4. $l + l' + s$ must be even.

In this case the set of modes in the eigenspace K must follow selection rules (1), (2) and (4) and the quasi-degenerate condition as before. Note that the matrix elements for rotation are real and symmetric whereas those for poloidal flow are imaginary and antisymmetric. The perturbation matrix $[\mathcal{H}_{n',l'l}^{m'm}]$ is hermitian for both cases and will have real eigenvalues.

4. Results

4.1. Differential rotation

We show in this section that QD treatment would give non-zero even coefficients a_{2q} even in absence of the centrifugal term and their effect on a_{2q+1} is indeed small as argued by Lavelly & Ritzwoller (1992). The determination of even splitting coefficients due to differential rotation is important as this may be used to remove the effect of rotation from the observed splitting coefficients to isolate the effect of magnetic field and other large scale flows in the observed splitting coefficients. However, if DPT is used, only the odd coefficients a_{2q+1} are non-zero if we neglect the centrifugal force which is second order in Ω . Further, in this approximation only the North-South symmetric component of rotation gives non-zero frequency shifts. Lavelly & Ritzwoller (1992) applied the QDPT to differential rotation to find that for intermediate l modes ($l \sim 50$) the quasi degenerate coupling will have little effect on the modal frequencies and can be ignored for all practical purposes.

It is easy to verify from equation (13) that for pure rotation ($\mathbf{v} = \Omega(r, \theta)r \sin \theta \hat{\phi}$) the symmetric matrix elements are odd functions of m . Hence from equation (6) and (11) one can infer that the perturbed frequency will have both odd and even splitting coefficients. It can be easily shown that there will be no additional effect in QDPT due to component w_1^0 of rotation velocity as the off-diagonal elements in the resulting matrix would vanish. Thus

the leading effect of rotation arises from w_3^0 term. We calculate this contribution by using

$$w_3^0(r) = \begin{cases} 34.9 \text{ m s}^{-1} & \text{if } r \geq 0.7R_\odot \\ 0, & \text{otherwise.} \end{cases} \quad (19)$$

This value is chosen such that the DPT gives a value of a_3 close to the observed value for most modes trapped in the convection zone. The QDP treatment modifies the odd splitting coefficient la_1 by up to 0.4 nHz (see Fig. 2a) and la_3 by up to 0.2 nHz, which are a couple of orders of magnitude smaller than the typical errors in these coefficients. In Figure 2b we plot the splitting coefficient la_2 for all the modes with frequency less than 4.5 mHz and $l \geq 10$, against r_t^{nl} , the lower turning point of the mode.

The calculation has been done using an equation similar to equation (11) but for all the modes in the neighborhood of radius 100 μ Hz about the central mode. The mathematical details of the calculation has been discussed in §3.2 (see equations (14) & (15)). The maximum value of $la_2 \sim 30$ nHz which may be significant depending upon the magnitude of the large scale flow or magnetic field perturbations. Note that the effect of centrifugal force on la_2 also happens to be of the same order (see Fig. 5 of Antia, Chitre & Thompson 2000). We have emphasized earlier that in order to spot the signatures of the large scale flows and magnetic fields we need to remove the effect of rotation on a_2 .

It has been found from Doppler measurements that there exists a hemispheric asymmetry in surface rotation having an angular dependence $\partial_\theta Y_2^0$ (e.g., Hathaway et al. 1996). This component has an amplitude of $w_2^0 = -7.8 \pm 0.3 \text{ m s}^{-1}$, which indicates that the southern hemisphere was rotating slightly faster than the northern hemisphere during the period of the data. We have also calculated the splitting coefficient la_2 due to north-south asymmetry assuming it is constant throughout the convection zone and they happens to be small with $la_2 \lesssim 0.1 \text{ nHz}$.

4.2. Meridional circulation

In this section we investigate theoretical frequency shifts due to meridional circulation. We start with $s = 2, t = 0$, which is the dominant component in the observed meridional flow near the surface. In our analysis, we have included all f- and p-modes with frequency less than 4.5 mHz and $l \geq 10$. We consider a meridional circulation with one cell in each hemisphere and maximum horizontal velocity at the surface equal to 30 m s^{-1} which is consistent with the Doppler measurements and ring diagram analysis. This gives $u_0 = 9 \text{ m s}^{-1}$ in equation (4). From equations (17) & (18) we see that the coupling matrix for poloidal flows is Hermitian with zero diagonal elements. This means that degenerate perturbation treatment cannot be applied to calculate the frequency shifts and it becomes essential to use the QDPT, unlike for rotation where QDPT just provides a second order correction. In presence of zero diagonal elements of the matrix $[\mathcal{H}_{ij}]$, equation (11) for the frequency shift for coupling between two modes simplifies to,

$$\delta\nu = \frac{\omega'_2 - \omega_2}{2\pi} \sim \frac{\mathcal{H}_{12}^2}{4\pi\omega_2\Delta}. \quad (20)$$

It may be noted that the sign of the frequency shift for the central multiplet with ω_{ref} depends on the sign of $\Delta = \omega_{\text{ref}}^2 - \omega_1^2$, where ω_1 is the nearest mode to the central frequency. If there are many modes with frequency close to frequency of the central mode, then we can expect these contributions to be added. In this case, if the sign of frequency differences are not the same, the terms will partially cancel each other. If for some pair of modes which satisfy the selection rules, the frequency difference is very small, then their frequencies would be shifted significantly.

In Figure 3 we show an example of the frequency shift $\delta\nu(m)$ of the multiplet $(n, l) = (1, 292)$, which was also considered by Roth & Stix (2008). The Wigner $3j$ symbol with $t = 0$ (implying $m' = m$) in equation (13) is an odd function of m and so $\delta\nu(m) \propto \mathcal{H}_{12}^2$ is symmetric about $m = 0$ for all the multiplets. Another important point to note from

equation (20) is that $\delta\nu \propto u_0^2$. This has also been verified by numerical calculations. The maximum shift we get for this multiplet from our calculations is ~ 8.5 nHz in contrast to Fig. 2 of Roth & Stix (2008) where they obtain a maximum shift of $0.1 \mu\text{Hz}$. On comparison with their equation (15) we find a difference of a factor of 2 in the first term in the expression of $H_s(r)$. Even after using their version of equation (15) in our calculations we were not able to reproduce the large shifts reported by them. The reason for this discrepancy is not clear. One possibility is normalization of velocity amplitude. The velocity decreases rapidly with height and if the normalization is applied at higher level, then the entire velocity profile will be scaled up. In these calculations we have normalized u_0 by comparing it with the surface velocity. We find that the peak value of $v_s^t(r)$ in Figure 1 occurs a little below the surface. For instance for a flow with $s = 2$ and a velocity of 30 m s^{-1} near $r = R_\odot$, this peak in $v_s^t(r)$ happens to be 72 m s^{-1} at $r = 0.996R_\odot$. However, in reality such a rapid increase in v_s hasn't been found from local helioseismology which can probe up to a depth of $0.96R_\odot$. Hence, in our opinion the theoretical frequency shift calculated using such a radial profile of $v_s^t(r)$ is an upper limit to the actual shift. Ideally, we should normalize u_0 to get the maximum value of the horizontal velocity to be 30 m s^{-1} . That will bring down the splitting coefficients by a factor of 4 or more. On the other hand, if we normalize the velocity further up then for the same value of velocity the calculated splitting coefficients would go up. However, that is not realistic as in that case the maximum velocity would be much larger than the observed value. In Figure 4a,b we plot the frequency shifts averaged over m for each multiplet where as Figure 4c shows the splitting coefficient la_2 calculated for all the multiplets.

We consider only even values of s so that the meridional flow does not have cross equatorial components. As we increase s , selection rules allow more and more multiplets in a radius of $100 \mu\text{Hz}$ to couple and there are many more instances of ‘near degeneracy’, so that the $\delta\nu \propto 1/\Delta$ in equation (20) for some multiplets becomes quite large. For example

the multiplets (17, 56) and (16, 64) which have a frequency difference of $-0.06 \mu\text{Hz}$ can be coupled by the meridional flow with $s = 8$ to give $la_2 \sim 480 \text{ nHz}$. In these calculations we have used $u_0 = 100 \text{ m s}^{-1}$. In Figure 3 we have plotted the frequency shifts for the pair of multiplets (15, 34) and (14, 40) also considered by Roth, Howe & Komm (2002), coupled by the same flow. The result for all multiplets with frequency less than 4.5 mHz and $l \geq 10$ is shown in Figure 5a,b. It is to be noted from Figure 5b that only some multiplets have a_2 larger than the errors in a_2 for those modes in observational data. It is only these multiplets which we may hope to detect in the observations. In this case we have taken the errors from the GONG data set centered at 19 November 2002. We present comparisons with GONG as well as MDI data in §4.4. Apart from the nearly degenerate modes the splitting coefficients of other modes are larger than that found for $s = 2$ with similar value of horizontal velocity near the surface. It may be noted that for large values of s the maximum value of horizontal velocity would be quite different from $v_s^t(r)$ because of the additional factor arising from the gradient of spherical harmonics (cf., Eq. 1). In the case where we normalize u_0 such that $v_s^0(R_\odot) = 30 \text{ m s}^{-1}$, we also obtain an increase with s in the splitting coefficients as reported by Roth & Stix (2008). This increase is not seen if the maximum value of the horizontal velocity near the surface is normalized to 30 m s^{-1} . Of course, observations near the solar surface do not show such large magnitudes for these higher order components of meridional flow. If realistic amplitudes are used then the effect will be negligible.

4.3. Giant convection cells

In this section we calculate the splittings due to poloidal flows with angular dependences that depend on longitude, ϕ . We consider the flow given by spherical harmonics $Y_8^4(\theta, \phi)$ and $Y_8^8(\theta, \phi)$ (also called sectoral rolls or banana rolls). This calculation is little more involved than that in §4.2 as a non zero t allows coupling between different m and m' in

equation (13). Hence it becomes important to take into account the effect of rotational splitting on Δ before calculating the effect of these kind of poloidal flows. It is easy to see from the properties of the Wigner $3j$ symbols that the $s = 8, t = 8$ flow couples the mode (n, l, m) with $(n', l', m \pm 8)$. Hence the difference of the square of frequencies Δ is no longer independent of m unlike in §4.2.

Let us consider the perturbation in the frequency of the multiplet (15, 34). The nearest multiplet to this happens to be (14, 40) with a frequency difference of $4.12 \mu\text{Hz}$ and the next one is (16, 28) with frequency difference $19.01 \mu\text{Hz}$. This is the same mode shown by Figure 3 of Roth, Howe & Komm (2002). We use the rotational splittings calculated from temporally averaged rotation rate as inferred from the GONG data to calculate Δ . The result of our calculation including only the nearest multiplet (14, 40) has been shown in Figure 6. The asymmetric frequency shift shown by the solid line in Figure 6a denotes the change in the frequency of the mode $(15, 34, m)$ due to coupling with the mode $(14, 40, m - 8)$ whereas the dashed line denotes the change due to coupling with $(14, 40, m + 8)$. As shown in equation (20) a crucial component of the shift comes due to the difference of the squared frequencies $\Delta_{m, m'}$ of the modes coupling according to the QDPT condition and the selection rules. The corresponding $\Delta_{m, m-8}$ and $\Delta_{m, m+8}$ are plotted in Figure 6b. The total shift is given by the sum of the solid and dashed curves. The couplings within a multiplet i.e., $(n, l, m) \rightleftharpoons (n, l, m \pm 8)$ happen to be zero because of the anti-symmetry of the matrix elements. The values of splitting coefficients la_1 and la_2 for the mode (15, 34) are calculated to be -12.2 nHz and -5.7 nHz and that for (14, 40) are 11.1 nHz and 5.3 nHz , respectively.

We repeat this calculation for all modes with frequency less than 4.5 mHz and find that some of the multiplets have quite high values of a_2 (see Fig. 9b). For example, the multiplet (18, 61) which couples with nearest multiplet (17, 69) with a frequency

difference of $-3.4 \mu\text{Hz}$. In Figure 7a we have plotted $\delta\nu(m)$ versus m for the coupling $(18, 61, m) \rightleftharpoons (17, 69, m-8)$ which seems to have a discontinuity at $m = -22$. This is due to the fact that $\Delta_{m,m-8}$ for this coupling also changes sign at $m = -22$. Note that two modes $(18, 61, m)$ and $(17, 69, m-8)$ having a mean frequency difference of $4.12 \mu\text{Hz}$ become ‘nearly’ degenerate at $m = -22$. This jump presumably gives rise to high values of splitting coefficients. The other coupling $(18, 61, m) \rightleftharpoons (17, 69, m+8)$ is smooth and so is the $\Delta_{m,m+8}$ as shown in Figure 7b by the dashed line. We also calculate the total shift experienced by the multiplet $(18, 61)$ while coupling with 3 nearest modes $(17, 69), (19, 55), (19, 53)$ and find no significant difference with Figure 7a. We have also shown a calculation for the asymmetric shifts for the multiplet $(14, 34)$ and $(14, 40)$ coupled due to a flow varying as $Y_8^4(\theta, \phi)$ in Figure 8.

The asymmetric shift due to these couplings give rise to non-zero odd splitting coefficients in addition to the even coefficients. Since rotation inversions neglect this contribution, the result may not be correct if the giant cells have significant amplitudes. The effect of giant cells on rotation inversions can be estimated by performing rotation inversion using odd splitting coefficients from these calculations. The resulting rotation rate should be subtracted from the actual rotation inversions. It is likely that if these multiplets are used for helioseismic inversion using the rotation kernel, they will give rise to distortion in the inverted rotation profile. The effect on the odd splitting coefficients, a_1 and a_3 is shown in Figure 9a,c in terms of observational errors in those multiplets. We use the theoretically calculated a_1 and a_3 to perform a 1.5d helioseismic rotation inversion using the formulation due to Ritzwoller & Lavelly (1991). We use 1.5d inversion as we have calculated only 2 splitting coefficients, a_1 and a_3 . For this purpose, we use only those modes which are present in a GONG data set and use the errors in those modes for inversions using a Regularized Least Squares method using the same smoothing as used for inverting real data (e.g., Antia et al. 1998). The results are shown in Figure 10, which shows the

resulting $w_1^0(r)$ and $w_3^0(r)$ in terms of the estimated errors. Because of presence of modes with large a_1, a_3 with $r_t \approx 0.7R_\odot$, there are some oscillations in this region, but their amplitudes are less than the estimated errors. Thus the effect on rotation inversion may not be significant even when the giant cells have velocity of 100 m s^{-1} . With increasing velocity the effect would be larger and it may be possible to detect this effect as it will give an oscillatory signal in rotation inversion at these depths. This has been pointed out by Roth, Howe & Komm (2002). They find a much larger effect as their estimate of frequency shift is generally larger than what we find. In real data the effect may not be as dramatic as shown by Figure 8 of Roth, Howe & Komm (2002) since many of the modes with large shifts in a_{2q+1} would yield large residuals in inversions, and any reasonable inversion would eliminate such modes. In our calculation, we found residuals going to about 4σ level and did not eliminate any modes. Thus it is difficult to put any limits on magnitude of flows using inversion results.

The even coefficient a_2/σ_2 is also shown in Figure 9b. If we find some multiplets with $0.6 < r_t/R_\odot < 0.8$ having magnitudes larger than the errors in observations as in Figure 9b we should be able to throw light on the flow velocities in giant cells. We shall look for such features in §4.4.

4.4. Comparison with observed data

We use 7 different data sets from the GONG observations, covering the late descending part of cycle 22 to end of cycle 23, i.e., from June 1995 to November 2008. We choose only those modes for which a_2 is available in the data sets. Since the different data sets can have different set of modes we repeat the calculation for all the 7 data sets. Most of the contribution to observed splitting coefficients appear to come from near surface effects, while we are interested in modes with turning point close to the base of the convection

zone. Thus we first separate the surface effects in the data by fitting a cubic spline in terms of frequency to $lI_{nl}a_{2k}/I_{nl0}Q_{lk}$ versus frequency. Here, I_{nl} is the mode inertia of the mode (e.g., Christensen-Dalsgaard 2002), while I_{nl0} is the mode inertia for the $l = 0$ mode at the same frequency, while Q_{lk} is a geometric factor as defined by Antia et al. (2001). After subtraction of the surface effect from the observed splitting coefficients, all the multiplets are sorted in the order of increasing r_t and then an error weighted 100 point average is applied. In Figure 11a, b we show the result of the averaging for the GONG 108-day averaged data sets centered on 19 November 2002 and 18 September 2007 respectively. To get an idea of the magnitude of the giant cell flows one can consider comparing the size of the valley and the hump in the region $0.6 < r_t/R_\odot < 0.8$ in the theoretical curve with that in the observation. It is difficult to make out if the expected signature is present in the observed data sets. In most cases no significant hump is seen in this region, though in some cases like in Figure 11a there is some hint of hump which is comparable to errorbars. The main problem with this approach is that the running mean tends to average modes with positive and negative values of a_2 , thus reducing the significance of the results. Thus it may be better to separate out these modes to look for the signal.

We have said earlier that only way to put an upper limit on the flow velocity is to look for signatures of nearly degenerate modes in the data. In order to do that we divide the multiplets from the theoretical calculations in two groups: one for which $la_2 > 10$ nHz and the other with $la_2 < -10$ nHz. Amongst 3700 theoretically evaluated multiplets we find only about 250 multiplets satisfying either criteria. Then we further search for these multiplets in the GONG data sets and perform an averaging over the available multiplets to get an estimate of a_2 from theory and error σ_2 in a_2 from the observations. Only about 10–12 of the 250 multiplets are usually found to be present in the GONG data sets. We find that for all the data sets, $|la_2| \sim 22$ nHz for theoretically calculated coefficients, whereas the error in la_2 (in observed set) is ~ 14 nHz for the $Y_8^4(\theta, \phi)$ flow with $u_0 = 100$ m s⁻¹.

The corresponding values for the $Y_8^8(\theta, \phi)$ flow with a $u_0 = 50 \text{ m s}^{-1}$ are 28 nHz and 13 nHz respectively. Since the observed data do not show these values (in both $> 10 \text{ nHz}$ and $< -10 \text{ nHz}$ sets) we can only put an upper limit on velocities in such flows. For this purpose we compare the a_2 values from theory with observational errors to calculate the confidence level of the upper limit. So we can say that up to a 1.5σ level we can rule out the $Y_8^4(\theta, \phi)$ dependent flow with $u_0 > 100 \text{ m s}^{-1}$ and the existence of the $Y_8^8(\theta, \phi)$ flow with $u_0 > 50 \text{ m s}^{-1}$ can be eliminated with a confidence level of 2σ . We have also performed some calculations with $Y_8^3(\theta, \phi)$ angular dependence and can say with a 1.5σ confidence level that such flows also cannot have $u_0 > 70 \text{ m s}^{-1}$. Our results for multiplets in all the 7 GONG data sets divided into two groups according to theoretical value of la_2 are represented in Table 1. MDI data also give similar results. By looking at detailed peak profiles of these abnormal modes in observed data it may be possible to put more stringent limits on velocity of such flows.

5. Conclusions

In this study we have calculated the effect of differential rotation, the meridional circulation and the giant cell flows on p-mode frequencies using quasi-degenerate perturbation theory. For toroidal flows like differential rotation, the quasi degenerate theory provides only a second order correction to the eigenfrequencies, whereas for the poloidal flows it becomes necessary to use the quasi degenerate treatment since the diagonal terms of the perturbation matrix vanishes. We agree with Lavelly & Ritzwoller (1992) that the effect of rotation on the odd coefficients is negligible and hence using the degenerate theory is sufficient. However, the even splitting coefficients a_{2q} are about one-half of the errors in observations and they might not be negligible while calculating the a_{2q} for other effects like the magnetic field. This contribution is comparable to the effect of centrifugal term.

The frequency shift due to N–S antisymmetric component of rotation rate vanishes in the degenerate perturbation treatment and it is necessary to use QDPT. We find that with realistic magnitude of velocities in the antisymmetric component, the computed splitting coefficients are very small and this effect may be neglected.

For a meridional circulation with maximum horizontal velocity at the surface of 30 m s^{-1} and one cell per hemisphere we find that $la_2 \sim 8.5 \text{ nHz}$ for multiplets with turning points r_t near the surface. Because of our choice of velocity field, the horizontal velocity increases rapidly with depth near the surface. This behavior is not seen in the Sun. In that case it may be more meaningful to choose velocity profile with a maximum value of 30 m s^{-1} , which occurs a little below the surface. In that case the splitting coefficients would need to be reduced by a factor of 4 or more, making them even smaller. The mean frequency shift due to meridional flow is found to be up to 12 nHz , which is much smaller than what is found by Roth & Stix (2008). The reason for this discrepancy is not clear. This could be due to differences in where the velocity is normalized to specified value.

In any case, la_2 is very small for multiplets with $r_t/R_\odot < 0.9$ coupled with single celled meridional circulation. This value is less than roughly one-seventh of the errors in the observed splitting coefficients. We also do not find any change with increasing the number of cells in the radial direction or by changing the depth of penetration of the meridional circulation while keeping the surface amplitude constant. This makes it impossible to comment on the return flow believed to be present at the base of the convection zone. When we increase the number of cells per hemisphere the selection rules allow more multiplets to couple with each other. In the process some of the nearly degenerate multiplets combine to give rather large values of la_2 . Interestingly, most of these nearly degenerate modes have turning points in the range $0.6R_\odot$ to $0.8R_\odot$. These purely meridional flows give frequency shifts which are symmetric about $m = 0$ and only give non zero values for even splitting

coefficients. The observed amplitude of these higher order components near the surface is rather small and with such amplitudes the effect is expected to be small. It appears that in general the magnitude of splitting coefficients due to $u_0 = 9 \text{ m s}^{-1}$ with $s = 2$ is smaller than that with $u_0 = 100 \text{ m s}^{-1}$ and $s = 8$, even after excluding modes with nearly degenerate frequencies. This could be due to a larger maximum horizontal velocity as well as larger radial velocity (for $s = 8$) or some geometric factors arising in the calculations.

In addition to this, we have also calculated the asymmetric frequency shifts caused due to giant convection cells with angular flow profiles given by $Y_8^4(\theta, \phi)$ and $Y_8^8(\theta, \phi)$. Our results differ significantly from earlier works of Roth, Howe & Komm (2002) and Roth & Stix (2008) who find the effect of poloidal flows on p-mode frequencies to be an order of magnitude larger than what we find. The asymmetric shifts also contribute to the theoretically calculated odd coefficients. We have performed a 1.5d rotation inversion on these coefficients to detect any discernible feature in the inverted profile. However, since the magnitude of the features in the inverted profile are smaller than the inversion errors we conclude that giant cells with $u_0 \leq 100 \text{ m s}^{-1}$ do not have much effect on the rotation inversion.

Finally we have analyzed some of the GONG data sets covering solar cycle 23 to look for possible evidence of giant cells. We do not find any signal of these flows in selected modes with large splitting coefficients and we can put upper limits on velocities of such cellular flows. From our analysis one can say that the existence of giant convection cells of $Y_8^4(\theta, \phi)$ angular pattern with maximum vertical velocities of 100 m s^{-1} can be ruled out with a confidence level of 1.5σ whereas cells with an angular dependence $Y_8^8(\theta, \phi)$ cannot have vertical velocities $> 50 \text{ m s}^{-1}$ with a confidence level of 2σ . It is important to remember here that the GONG data sets are averaged over 108 days, while MDI data sets over 72 days. This may be somewhat larger than the lifetimes of giant cells and hence the

signal may be averaged out. We can look at shorter data sets, but in that case the errors would be larger. Further, the convective cells are not expected to have smooth velocity profiles of the form used by us over the entire solar surface. That would also reduce the contribution to splitting coefficients.

Finally, we would like to point out that while the degenerate perturbation theory can be easily adopted for inversion because of linearity of effect and the form of perturbation which can be represented by appropriate kernels. In contrast, the effect of quasi-degenerate perturbation theory is nonlinear in velocity and further is mainly governed by frequency differences between nearly degenerate modes, rather than the matrix elements which depend on velocity profile. Hence it is difficult to use these shifts in inversions. For example, the main effect of flow with $s = 8$ is felt in modes with turning points close to $0.7R_{\odot}$, which happens to be close to the lower limit of region in which our flows were localized. But we have verified that this is just a coincidence by performing calculations with different lower boundary. The same set of modes is affected irrespective of lower boundary, because it is these modes that have small frequency differences. This is only determined by the value of s which determines the range of l values that are coupled. Thus various types of perturbations with the same coupling will give large splittings in these modes and it is difficult to identify the actual source of perturbation.

We thank the referee for useful comments and suggestions which have helped in improving the manuscript. This work utilizes data obtained by the Global Oscillation Network Group (GONG) project, managed by the National Solar Observatory, which is operated by AURA, Inc. under a cooperative agreement with the National Science Foundation. The data were acquired by instruments operated by the Big Bear Solar Observatory, High Altitude Observatory, Learmonth Solar Observatory, Udaipur Solar Observatory, Instituto de Astrofisico de Canarias, and Cerro Tololo Inter-American

Observatory. This work also utilizes data from the Solar Oscillations Investigation/
Michelson Doppler Imager (SOI/MDI) on the Solar and Heliospheric Observatory (SOHO).

Fig. 2.— (a) Odd splitting coefficients $l a_1$ as a function of r_t for the $\partial_\theta Y_3^0$ component of differential rotation (refer to equation (1)). (b) Same as (a) but for even splitting coefficient $l a_2$.

Fig. 3.— Frequency shifts as a function of azimuthal order m/l . The shift in the multiplet $(n, l) = (1, 292)$ due to coupling by Y_2^0 flow with $u_0 = 9 \text{ m s}^{-1}$ (solid line); $(n, l) = (15, 34)$ due to Y_8^0 flow and $u_0 = 100 \text{ m s}^{-1}$ (dashed line); shift for the multiplet $(n, l) = (14, 40)$ for the same flow and velocity (thick solid line).

Fig. 4.— Mean frequency shifts $\overline{\delta\nu}(m)$ as a function of (a) frequency ν and (b) turning point $r_t/R_\odot$ due to coupling by meridional flow with $s = 2, t = 0$. (c) Splitting coefficient la_2 as a function of lower turning point radius r_t .

Fig. 5.— (a) Mean frequency shift $\overline{\delta\nu}$ as a function of turning point $r_t/R_\odot$ due to coupling by large scale flow with $s = 8, t = 0$. (b) Splitting coefficient a_2 as a function of turning point radius r_t . The points denote the theoretical values of a_2/σ_2^{nl} for modes (n, l) . The errors σ_2^{nl} have been chosen from the GONG data set centered around 25 December 2002.

Fig. 6.— (a) The *solid line* gives the frequency shift because of interaction between modes $(15, 34, m)$ and $(14, 40, m - 8)$ due to the flow with an angular dependence $Y_8^8(\theta, \phi)$. The *dashed line* is the frequency shift due to interaction between modes $(15, 34, m)$ and $(14, 40, m + 8)$. The total shift in frequency for the mode $(15, 34)$ is the sum of the solid and the dashed lines. The frequency shift for the mode $(14, 40)$ is given by the *dotted line*. (b) $\Delta_{m,m-8}/2\nu$ (*solid line*) for the coupling $(15, 34, m) \rightleftharpoons (14, 40, m - 8)$; and $\Delta_{m,m+8}/2\nu$ (*dashed line*) for the coupling $(15, 34, m) \rightleftharpoons (14, 40, m + 8)$. These values are in μHz .

Fig. 7.— (a) The *solid line* gives the frequency shift because of interaction between modes $(18, 61, m)$ and $(17, 69, m - 8)$ due to the flow with an angular dependence $Y_8^8(\theta, \phi)$. The *dashed line* is the frequency shift due to interaction between modes $(18, 61, m)$ and $(17, 69, m + 8)$. The total shift in frequency for the mode $(18, 61)$ is the sum of the solid and the dashed lines. The frequency shift for the mode $(17, 69)$ is given by the *dotted line*. (b) $\Delta_{m,m-8}/2\nu$ (*solid line*) for the coupling $(18, 61, m) \rightleftharpoons (17, 69, m - 8)$; and $\Delta_{m,m+8}/2\nu$ (*dashed line*) for the coupling $(18, 61, m) \rightleftharpoons (17, 69, m + 8)$. These values are in μHz .

Fig. 8.— Asymmetric shift in frequency of the multiplet (a) (15, 34) (solid line) upon coupling with neighboring multiplets (14, 40) and (16, 28) in presence of large scale flow $s = 8, t = 4$. The dashed-dotted line is the shift for the mode (14, 40) due to coupling with (15, 34) and (13, 48). (b) Same as (a) but for (18, 61) (solid line) upon coupling with neighboring multiplets (17, 69) and (19, 55) in presence of large scale flow $s = 8, t = 4$. The dashed-dotted line is the corresponding shift in (17, 69) due to coupling with 2 nearest neighbors.

Fig. 9.— (a) a_1/σ_1 and (b) a_2/σ_2 and (c) a_3/σ_3 as a function of lower turning point radius r_t for the $Y_8^8(\theta, \phi)$ kind of flow with $u_0 = 100 \text{ m s}^{-1}$. The $\sigma_{1,2,3}$ are the errors in the corresponding observational splitting coefficients from the GONG data set centered about November 2002 (see Table. 1).

Fig. 10.— w_1^0 (solid line) and w_3^0 (dotted line) in terms of the respective errors are shown as a function of radial distance obtained from the 1.5d inversion of coefficients a_1 and a_3 shown in Figure 9.

Fig. 11.— $l a_2$ as a function of turning point radius r_t after averaging over 100 nearest points in r_t for GONG data set centered around (a) November 2002 and (b) 18 September 2007. The dotted line correspond to the $Y_8^0(\theta, \phi)$ flow; dashed to $Y_8^4(\theta, \phi)$; thick solid to $Y_8^8(\theta, \phi)$. The solid line with errorbars show the observed data points. To avoid congestion only a few representative errorbars are shown.

Table 1: Comparison of observed la_2 with theory for flows with an angular dependence $Y_8^t(\theta, \phi)$. The numbers in the GONG data set have the following correspondence with the date about which the 108-day GONG month is centered: (1) 29 June 1995, (2) 18 June 1997, (3) 18 September 2000, (4) 19 November 2002, (5) 23 July 2004, (6) 18 September 2007 and (7) 2 July 2008. For $t = 4$, $u_0 = 100 \text{ m s}^{-1}$ whereas for $t = 8$, $u_0 = 50 \text{ m s}^{-1}$. Note that for each t the group I of multiplets correspond to $la_2^{\text{th}} < -10 \text{ nHz}$ whereas the group II is for $la_2^{\text{th}} > 10 \text{ nHz}$. CL is the confidence level on the upper limit of u_0 .

Data set	t	I. $la_2^{\text{th}} < -10 \text{ nHz}$				II. $la_2^{\text{th}} > 10 \text{ nHz}$
